To
Mogens Larsen
on the Occasion of his Eightieth Birthday

Mogens Larsen, at Ankara Museum of Anatolian Civilizations, March 2016.
© Vanessa Tubiana-Brun.

The 3rd Kültepe International Meeting took place the very year Mogens Larsen turned eighty. We wish to dedicate the proceedings of KIM 3 to Mogens as a token of friendship, and for his outstanding contribution to Old Assyrian studies.¹ If the Old Assyrian Text Project (OATP) was founded in Leiden in 1999, it really became efficient at the beginning of the twenty-first century when Mogens convinced the Carlsberg Foundation to support the project for twelve years. Copenhagen became the centre of the OATP, where Mogens built up a great team of young scholars dedicating all their time to the Old Assyrian period. Within the OATP, five PhDs were defended in Copenhagen, and these young colleagues were able to extend their researches through postdoctoral fellowships.² The OATP group met at least once a year in the city of Carsten Niebuhr, discussing topics and texts, exchanging data, dinners, and drinks. Last but not least, Mogens has published one of the largest Kültepe archive, making available in a few years more than 1200 new texts (AKT 6, *The Archive of Šalim-Aššur's Family*). Old Assyrian studies owe a lot to Mogens!

Fikri Kulakoğlu & Cécile Michel

¹ Mogens Larsen was presented a Festschrift in 2004: Jan Gerrit Dercksen (ed.), *Assyria and Beyond: Studies Presented to Mogens Trolle Larsen* (PIHANS C). Nederlands Instituut Voor Het Nabije Oosten, Leiden.

² The topics were varied: Karen Jensen, 'Marriage and Divorce in the Old Babylonian and the Old Assyrian Periods' (2003); Gojko Barjamovic, 'A Historical Geography of Ancient Anatolia in the Assyrian Colony Period' (2005); Thomas K. Hertel, 'Old Assyrian Legal Practices' (2008); Agnete W. Lassen, 'Glyptic Encounters: A Stylistic and Prosopographical Study of Seals in the Old Assyrian Period – Chronology, Ownership and Identity' (2012); Xiaowen Shi, 'Anatolians as Seen through the Old Assyrian Texts' (2013). Another PhD thesis defended in Chicago benefited from a year fellowship at Copenhagen, within the OATP: Edward P. Stratford, 'Archives, Agents, and Risk: An Account of Assyrian Commerce in 1894 BC' (2010).

4. ARCHAEO-MAGNETISM AT KÜLTEPE: UNTANGLING THE ORDER OF FIRE EVENTS IN ANTIQUITY

Pinar Ertepinar*, Cor Langereis*, Andy Biggin**, Lennart V. de Groot* & Fikri Kulakoglu***

Introduction

Archaeomagnetism is the study of burnt or fired archaeological artefacts with the aim of determining short term variations in the Earth's magnetic field over the past thousands of years, also called the paleosecular variation (PSV). A second and ultimate outcome regarding the archaeological use of these studies is to provide a dating tool for the fire events once a good master curve for the region is constructed using the well-dated material. Commonly studied *in-situ* features include kilns, hearths, ovens, and fires for paleo directions and intensities while *ex-situ* artefacts like ceramics and tiles can be used for paleointensity studies only.

The characterization of PSV is particularly important for understanding the geodynamo behaviour of the Earth. Based on the archaeomagnetic and historical or well-dated lava flow measurements all around the world, a number of global field models have been developed. The most recent models are pfm9k.1b¹ and SHA.DIF.14k² and are now widely used, having a better resolution compared to the older models. However, there are local variations in the field that are not detected by global field models such as the intensity high over the Levant region that occurred around 1050–750 BC, recently described by Shaar³ as the 'Levantine Iron Age Anomaly (LIAA)'. In addition, the present data for directions is mainly derived from the sites in Eastern Europe and that causes a bias in the field models. Although the

existing data around Turkey and the global field models give a first approximation of the ancient field, the use of archaeomagnetism as a dating tool requires a well-established PSV curve for this large region.

The main objective of this study is to solve (partly) the timing and character of the demise of this settlement by comparing our archaeomagnetic results from different parts of the settlement. We will argue that the abandonment of the site was not the result of a single big catastrophic event and we conclude that the site must have been destroyed (burned) in various stages.

Background Information on Geo/Archaeo Magnetism

The magnetic field of the Earth changes continuously and non-uniformly through time and space. The recent behaviour of the field is well known from the observatories. The historical changes (approximately last four hundred years) are reconstructed from the navigational observations while older records (past thousands of years) are derived through archaeomagnetism.

Almost all kinds of earth materials have magnetic minerals in their composition capable of recording the Earth's magnetic field primarily during the deposition process of the rocks, and afterwards, if disturbed with an agent like underground water, fire, pressure, etc. This record is called the 'Natural Remanent Magnetization (NRM)' and can be measured by using magnetometers. The NRM is expressed by three components; declination, inclination (directions of the vector in the horizontal and vertical plane, respectively), and intensity (the magnitude of the vector). Obtaining directional results and intensities require different treatments. In archaeomagnetic studies, in general, directional analyses are more straightforward compared to intensities. The only condition for reliable directions is the availability of the *in-situ* materials. Archaeointensity experiments on the other hand, are more difficult and time-consuming.

The success of the experiments is highly dependent on the material properties (explained in section 4) and the possible alteration of magnetic minerals — that can occur during repetitive heatings in the experimental procedure — also alters the results (whereas the directions are not significantly affected). There are additional problems, such as the anisotropy that can be introduced in the manufacturing process of archaeological artefacts, and the cooling rate effect caused by the time lag between actual and experiment cooling. Depending on the nature of the problem, all these effects should be

monitored carefully prior, during, or after the experiment. Therefore, intensity experiments are more time consuming and have much lower success rate compared to obtaining directions.

Once all three components are well established from a fair number of well-dated data points covering a sequence of time intervals over a specified region (e.g. Turkey), it is possible to construct curves that define the magnetic field behaviour for that region that forms the basis for archaeomagnetic dating.

Sampling

For directional measurements, the sampling was done with a custom-made water-cooled drill to take oriented cylindrical cores of 2.5 cm diameter. Diamond drill bits and a non-magnetic orientation device were used to avoid magnetic contamination. Unoriented cores, pot sherds, and mud-brick fragments were sampled for archaeointensity experiments. For statistical confidence, we took at least seven samples (but generally more, up to forty-six) from each set, and we sampled as many different building materials as possible.

In the field season of 2007 and 2008, we collected thirteen sets of samples; three from the mound (the upper town) and ten sets from Kârûm part (the lower town). Two of the mound sets, KT1 and KT2, are from Warşama Palace and Güney Palace, respectively, with corresponding Kârûm levels of Ib and II. Both palaces were completely destroyed by intense fires. These sets are composed solely of mud-bricks. The third mound set (KT12) is from the vitrified mud-bricks of an Early Bronze Age level. The Kârûm sets consist either solely of ignimbrites or of a combination of mud-bricks and ignimbrites. The mud-bricks in the settlement were used as building stones while the ignimbrites were used as foundation stones. All ten sets are from different rooms where five sets are from level Ib and the other five are

from level II. The site is only a few kilometres away from a massive stratovolcano, and the types of ignimbrites used in the foundation show considerable variation. In some parts of the settlement, the fire was so intense that the mud-bricks were molten and became vitrified. The locations and the details of sampling sets are given in Figure 4.1 and Table 4.1.

Rock Magnetism

The rock magnetic experiments are preliminary checks for the suitability of the material for archaeomagnetic studies. For all sets, room temperature bulk magnetic susceptibilities and thermo-magnetic curves (Curie curves) were determined for the identification of the magnetic carriers and thermal stability. Based on the results from these experiments, additional checks including the hysteresis loop, Isothermal Remanent Magnetization (IRM) acquisition, and First Order Reversal Curve (FORC) diagram measurements were performed on nine sets that appeared suitable for archaeointensity measurements (Fig. 4.2).

The room temperature bulk magnetic susceptibilities of all samples are measured to calculate the

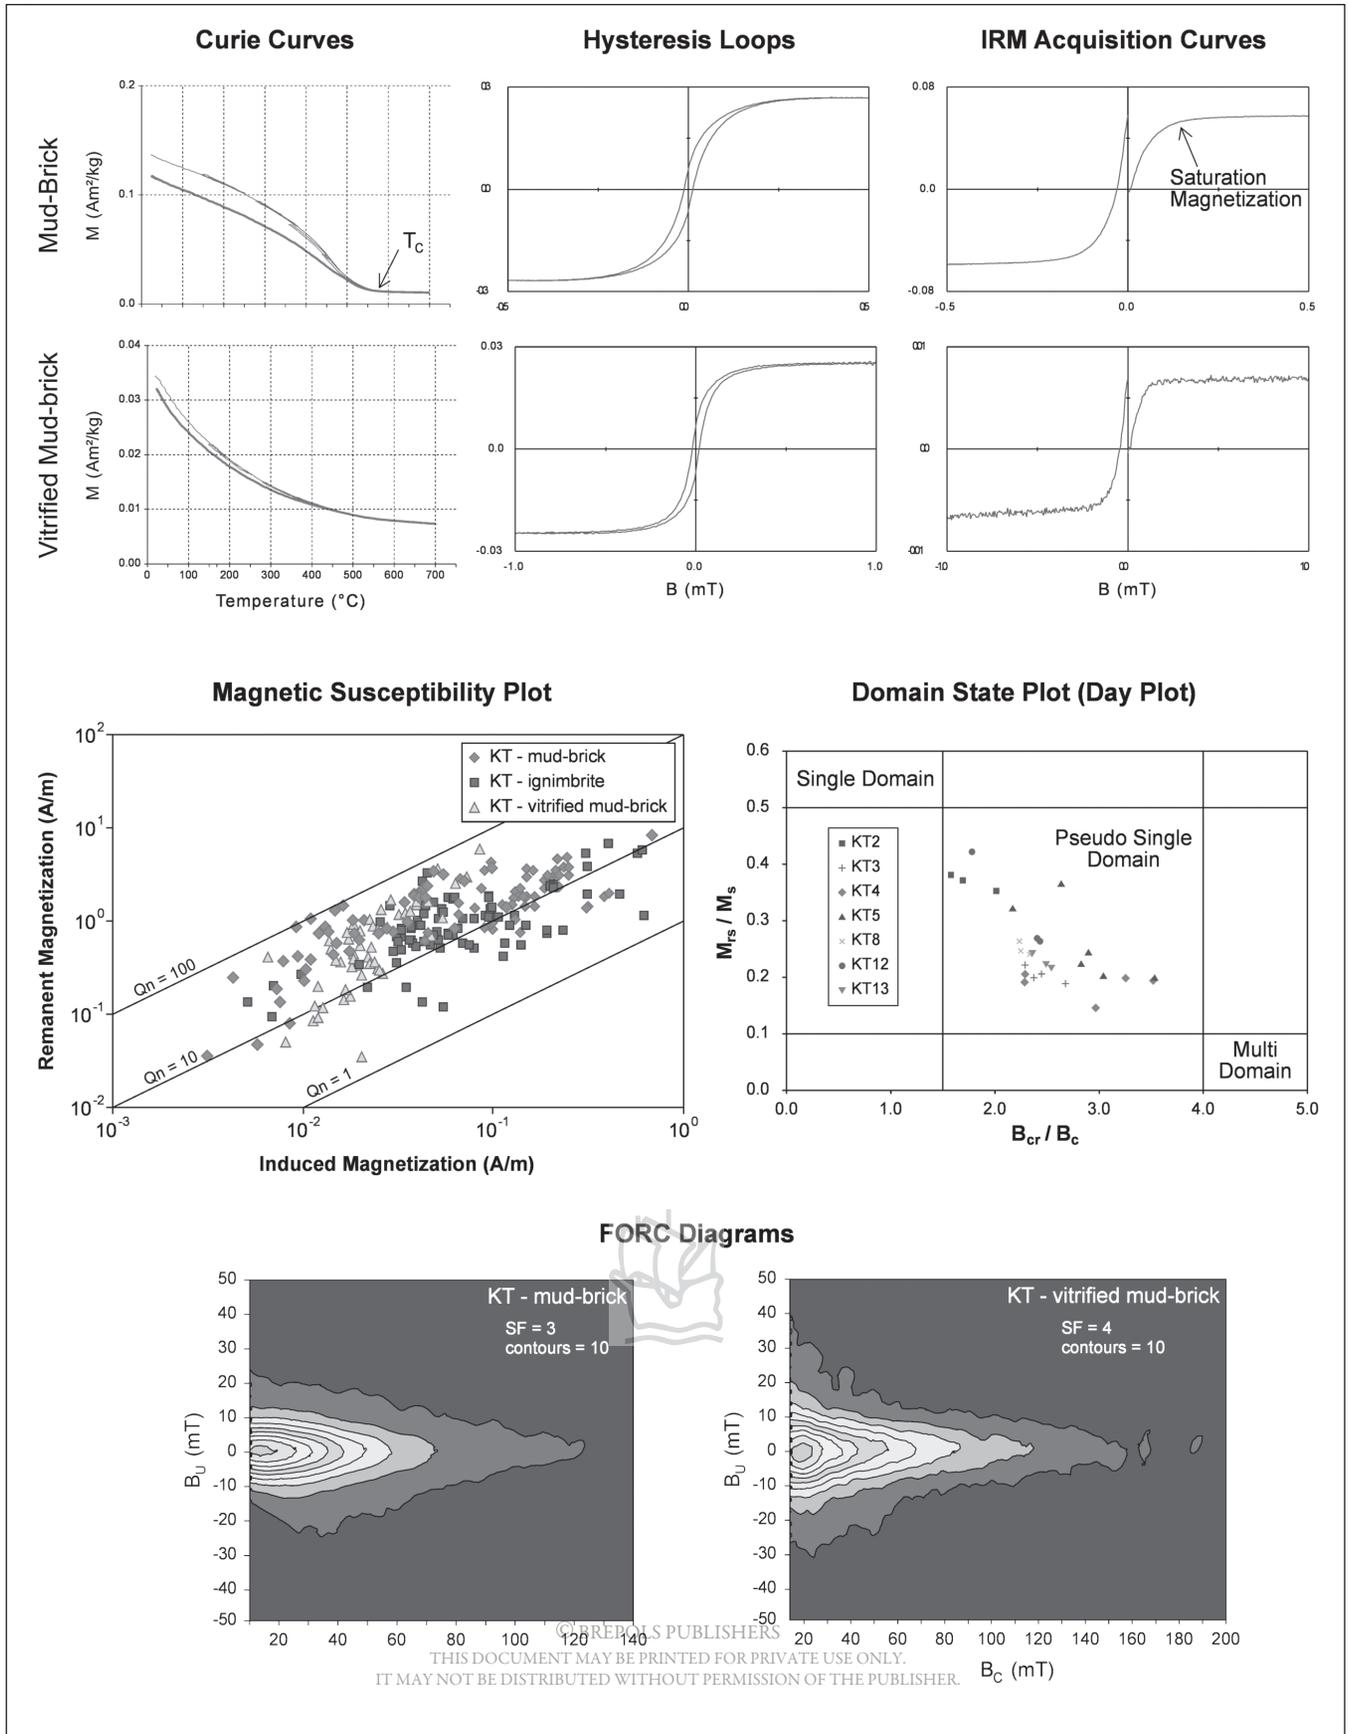

Figure 4.2. Rock magnetic properties representative of each building material. Figures by the authors.

Koenigsberger Ratio (Q_n), which is an appropriate measure to check whether the samples carry a stable thermo-remanent magnetization (TRM) rather than a recent viscous remanent magnetization (VRM). For all three types of building materials, TRM strongly dominates ($Q_n > 1$) providing a positive stability test.

Thermo-magnetic measurement is the primary method for the identification of the magnetic carrier since each mineral has its own Curie temperature (T_c). A single Curie point on the curve indicates the dominance of a single carrier. The difference between the cooling and heating curves indicates alteration. The experiments run on mud-bricks show magnetite magnetization with near reversible heating/cooling curves with a single Curie temperature at ~ 580 °C. The hyperbolic curve from the vitrified mud-brick, on the other hand, did not allow identification of the magnetic carrier. The curves from the ignimbrites have a single T_c at ~ 580 °C but display significant difference on heating and cooling curves indicating alteration, and therefore discarded from archaeointensity analysis.

Hysteresis loop parameters and IRM acquisition curves are helpful to specify the domain state of the magnetic mineral that is essential for archaeointensity measurements. In general, single domain (SD) particles are ideal, pseudo single domain (PSD) particles are well-behaved, and multi domain (MD) particles are problematic, as also are the minerals with high saturation fields and magnetic interactions. The results of all measurements on mud-bricks and vitrified mid-bricks show that the samples consist only of PSD grains (Day plot in Fig. 4.2),⁴ and there is no indication of a high coercivity mineral in the IRM acquisition curves since all the samples are saturated in low fields below ~ 200 mT.

A FORC diagram is a second check for the domain state and provides additional information on the interaction fields of magnetic minerals.⁵ The mud-bricks and vitrified mud-bricks have a symmetrical FORC diagram with one closed inner contour and a very narrow contour spreading along the ordinate indicating the assemblages are dominated by non-interacting PSD grains.

Demagnetization, ChRM, and Directional Results

Demagnetization

Two techniques, thermal (Th) and alternating field (AF) demagnetization, were used to measure the magnetic remanence in each sample. Thermal experiments were performed using a cryogenic magnetometer while the AF measurements were carried out on a high precision robotized cryogenic magnetometer. At least fourteen samples from each set were demagnetized with small incremental steps up to a maximum of 580 °C or 100 mT. The demagnetization results were plotted in orthogonal projection diagrams.⁶ One representative diagram from each type of building material is plotted in Figure 4.3. All mud-bricks and the majority of ignimbrite samples have single component demagnetization diagrams uniformly decaying to the origin. This indicates either the primary magnetization (the NRM gained during manufacture) or, if present the secondary event (in this case the TRM recorded during fire) that caused the material to (re)gain remanent magnetization, is fully recorded. Occasionally, the demagnetization diagrams show two components pointing to 'partial burning' (meaning the samples were not heated to their Curie temperatures). In this case, the low-temperature component (marked as LT in Fig. 4.3) can be interpreted as the record from the burning event and the high-temperature (HT) component is the sample's original magnetization.

Characteristic Remanent Magnetization (ChRM)

Directions

The remanent magnetization directions are interpreted via the principle component analysis.⁷ The mean directions were calculated according to Fisher.⁸ The acceptance criteria for maximum angular deviation (MAD) of individual directions and the α_{95} cone of confidence of the means are taken as 10 °, but values are typically much lower than that. The quality of the cluster is assessed with the dispersion parameter (k) where we require $k > 100$. The results of directional analyses are reported in Table 4.2.

The sets that are composed solely of mud-bricks (KT1, KT2, and KT3) produced good quality demagnetization diagrams and well-defined ChRM directions with high k values (200–600) and low α_{95} (< 1.7).

Site	Treatment	n/N	Dec	Inc	k	α_{95}
KT1	Th, AF	25/26	5.0	56.0	300.0	1.7
KT2	Th, AF	38/44	-11.3	50.3	215.7	1.6
KT3	Th, AF	13/14	2.9	48.4	603.9	1.7
KT4	Th, AF	11/15	1.0	42.1	533.2	2.0
KT5	Th, AF	61/70	0.2	44.2	363.9	1.0
<i>KT6</i>	<i>Th, AF</i>	<i>NOT BURNT</i>				
<i>KT7</i>	<i>Th, AF</i>					
KT8	Th, AF	14/17	2.2	41.4	348.9	2.1
KT9	Th, AF	10/16	-6.5	57.0	385.3	2.5
<i>KT10</i>	<i>Th, AF</i>	<i>NOT BURNT</i>				
<i>KT11</i>	<i>Th, AF</i>					
KT12	Th, AF	53/53	3.9	59.7	243.7	1.3
KT13	Th, AF	15/18	-2.6	45.9	154.8	3.1

Out of five sets that are composed only of ignimbrites, the demagnetization diagrams of four sets (KT6, KT7, KT10, and KT11) are of good quality again, however, with completely random directions (the rejected sets in Fig. 4.3). The ChRM directions with no cluster indicate an insufficient burning where the samples still carry their original magnetization. The samples from the last ignimbrite set, KT9, were either fully burnt providing a meaningful direction or sufficiently heated to have a clear well-determined LT component in the demagnetization diagram that we consider representing a ChRM due to firing. This set is also of good quality with $k > 300$, $\alpha_{95} < 2.5$.

There are four sets (KT4, KT5, KT8, and KT13) that are composed of both mud-bricks and ignimbrites. The ignimbrite samples from these sets have either single or two component demagnetization diagrams whereas the mud-bricks are single component. When the LT component of the ignimbrites are isolated, the directions obtained from these two different building materials become extremely consistent within each set providing well-defined ChRM directions with $k > 155$ and $\alpha_{95} < 3.1$.

The oldest (Early Bronze III) set, KT12, is entirely composed of vitrified mud-bricks. The demagnetization diagrams are single component and the magnetization is completely removed at ~ 500 °C pointing to Titanium-poor magnetite as the carrier (where the hyperbolic

Curie curves (Fig. 4.2) did not allow identification of the magnetic mineral). The set displays a well-defined ChRM with $k = 244$ and $\alpha_{95} = 1.3$.

Out of the thirteen sets of samples from the site, four sets turned out to be not burnt. The remaining nine sets are considered to be of good quality with IGRF corrected declinations between 348.7° and 5.0° and inclinations between 41.4° and 59.7° .

Archaeointensity Experiments and Results

The Experimental Procedure

Regarding the difficulties in obtaining a reliable archaeointensity estimate (discussed in section 2), it is crucial to employ different techniques, if possible. In this study, we adopted three protocols for the archaeointensity experiments. These three methods were also applied to a large set of volcanics by de Groot⁹ who concluded that the results were remarkably accurate if the results of two or more methods mutually agreed, testifying to the importance of not adhere to just one protocol. A brief description of each method is given below.

Thermal Thellier-Thellier Technique

The method developed by Thellier and Thellier¹⁰ is based on progressively removing the NRM and replacing it with a laboratory TRM via step-wise heating. First the sample is heated to a particular temperature and then cooled to room temperature in a laboratory field, B_{lab} . Next, a second heating is performed to the same temperature and cooled down but this time in the opposite field direction ($-B_{lab}$). Vector subtraction of these two steps allows the determination of the NRM remaining at each temperature step and the partial TRM (pTRM) gained. The ancient field strength is proportional to the slope of the best fit line of NRM against pTRM.

In this study, we followed the IZZI protocol¹¹ which is a combination of Coe¹² and Aitken¹³ modifications of the method where an in-field step is followed by a zero-field step (IZ) or vice versa (ZI). A custom-built orientation tray was used to align each sample's NRM with the applied field direction, reducing the effects of ani-

¹² Coe 1967.

¹³ Aitken 1988.

sotropy during TRM acquisition.¹⁴ The acceptance criteria, adopted from Coe¹⁵ and supplemented by those of Selkin and Tauxe¹⁶ are as follows:

1. The number of points used for the best fit line (N) ≥ 5
2. The ratio of standard error of the slope to absolute value of the slope (β) < 0.1
3. The NRM fraction (f) ≥ 0.4
4. Quality factor (q) > 5 , where most results are higher than 10
5. The number of successful pTRM checks ≥ 3
6. The ratio of difference between the pTRM check and relevant TRM value to the length of the selected NRM-TRM segment (DRAT) < 10 per cent
7. MD behavior of the interpreted segment of the NRM-TRM plot is assessed by the curvature statistic, $|k|$, and the acceptance limit is taken as 0.164.¹⁷

Microwave Technique

As described in the previous sections, the major problem with the archaeointensity experiments is the mineral alteration caused as a result of multiple heatings. The basic principle of the method is identical with what is described in the thermal Thellier method. The only technical difference is that the excitation of electrons (hence, the heating) takes place only on magnetic minerals by means of microwaves instead of heating the whole sample which is the case for the thermal Thellier method.

We performed twenty-one microwave measurements on one to five samples from each set. Possible influence of anisotropy was checked for by comparing the direction of the magnetization acquired with that of the applied field. In all cases, no significant systematic off-sets were observed suggesting that anisotropy was negligible. To monitor thermo-chemical alteration, pTRM checks were performed after every two double-treatments. The same selection criteria were employed as in the TT experiments.

Multi-Specimen Method

To reduce the effect of non-ideal MD behaviour and progressive alteration during TT experiments,¹⁸ Dekkers and Böhnelt proposed a method, the 'multi-specimen parallel differential pTRM method', here referred to as MSP-DB. The idea behind the method is simple: to overprint an ancient TRM with a laboratory pTRM induced at a temperature much lower than the Curie temperature in a laboratory field applied in the same direction as the TRM. The initial suggestion that this protocol was domain-state independent, however, did not hold; Fabian and Leonhardt¹⁹ proposed an addition to the protocol to correct for MD behaviour. As a rule, we apply the domain-state corrected protocol, referred to as MSP-DSC. The experiments were run on four samples from each set. The MSP experiments were accepted if the average progressive alteration, $\epsilon_{\text{alt}} < 3$ per cent. For the MSP-DCS protocol there is an additional requirement where, Db , the difference between the theoretical ($b = -1$) and the actual value of y-axis intercept of the best-fit line should be smaller than 10 per cent. If this requirement was not fulfilled, implying that the MSP-DSC protocol did not properly correct for MD behaviour, we used the MSP-DB protocol provided that the ϵ_{alt} is still less than 3 per cent.

Archaeointensity Results

The measurements were carried out on eight sets (one set of vitrified mud-brick and seven mud-brick sets) out of thirteen. In addition, from set KT3, three microwave measurements were performed on sherds. Four sets (KT6, KT7, KT10, and KT11) were discarded based on their directional results and one ignimbrite set (KT9) due to its rock magnetic properties. Five sets successfully yielded a result in all three methods. Figure 4.3 shows an example of a successful and a failed measurement from each method and the results are reported in Table 4.3. Out of forty-nine TT and MW measurements, forty were successful yielding a success rate of 82 per cent. From eight sets of MSP measurements, seven were successful either with DSC or DB solution. The results from different protocols reasonably agree with each other and no systematic differences were observed between the TT and MW results from the same sample sets. For the samples of same origin, if the cooling rate effects are present, it is expected to be enhanced

in MW estimates and make them systematically higher than thermal estimates that use longer cooling times.²⁰ The agreement in TT and MW results suggests that no cooling rate correction is required for the data as a whole. Moreover, the remanence in the samples is predominantly carried by PSD grains (Fig. 4.2) for which the cooling rate effect on (p)TRM magnitude has been experimentally verified as small.²¹

From the mud-brick set KT1, we made one TT measurement which has failed and one MW measurement in which the MSP-DB result obtained from four data points is in line with the value within 5 per cent.

The samples from KT2 and KT4 produced good quality TT results, however, failed in all MW experiments either due to noisy NRM-TRM plot, indestructible NRM or MD behaviour. We were not able to perform the MSP method on KT2 because there were not enough samples, so we present an intensity value based on one TT measurement. The MSP result from KT4 is of good quality with minor alteration and $Db < 10$ per cent allowing to opt for the domain corrected solution.

The majority of TT and MW measurements from the sets KT3 (mud-bricks and sherds), KT5, KT8, KT13 (mud-bricks), and KT12 (vitrified mud-bricks) have passed the selection criteria, producing high quality NRM-TRM plots. The samples from KT5 produced two low and two high TT results in which the lower values are in line with the MSP-DSC result and the higher values are in agreement with the MW results. Among all sets, KT8 has the most consistent results in both individual sample

level and mean intensities obtained using all three protocols. The measurements from the vitrified mud-bricks of KT12 produced the highest intensity value calculated from three protocols. The samples from KT13 produced well behaved NRM-TRM plots from TT and acceptable results from MW and MSP methods.

The intensity results obtained from forty successful measurements using three protocols range between 51.48 and 62.26 μT .

Discussion

Evaluation of Directions and Intensity Results

The directional results from this study, corrected for local declination at the time of sampling, are relocated to Kayseri as the approximate centre of Turkey (lat: 38.851 °N, long: 35.631 °E), and plotted against the data from GEOMAGIA50.v3.2²² (downloaded on December 2018 from the countries within ~1600 km radius), and the global geomagnetic field models SHA.DIF.14k and pfm9k.1b calculated at Kayseri (Fig. 4.4a).

A first observation is that the model SHA.DIF.14k fits very well with both our earlier directional observations and the results from this study, including the large declination swing to nearly 20 °E around 2000 BC (Fig. 4.4a), that was not detected by earlier models. Nor is it recorded by the heavily smoothed pfm9k.1b model. The inclination values of the sets are shallower than the model predictions by some 10° but in line with the general trend of the model. By their nature, field models are usually considerably smoother than the actual field

²⁰ Poletti *et al.* 2013.

²¹ For example: Biggin *et al.* 2013; de Groot *et al.* 2013; Yu 2011.

²² Brown *et al.* 2015.

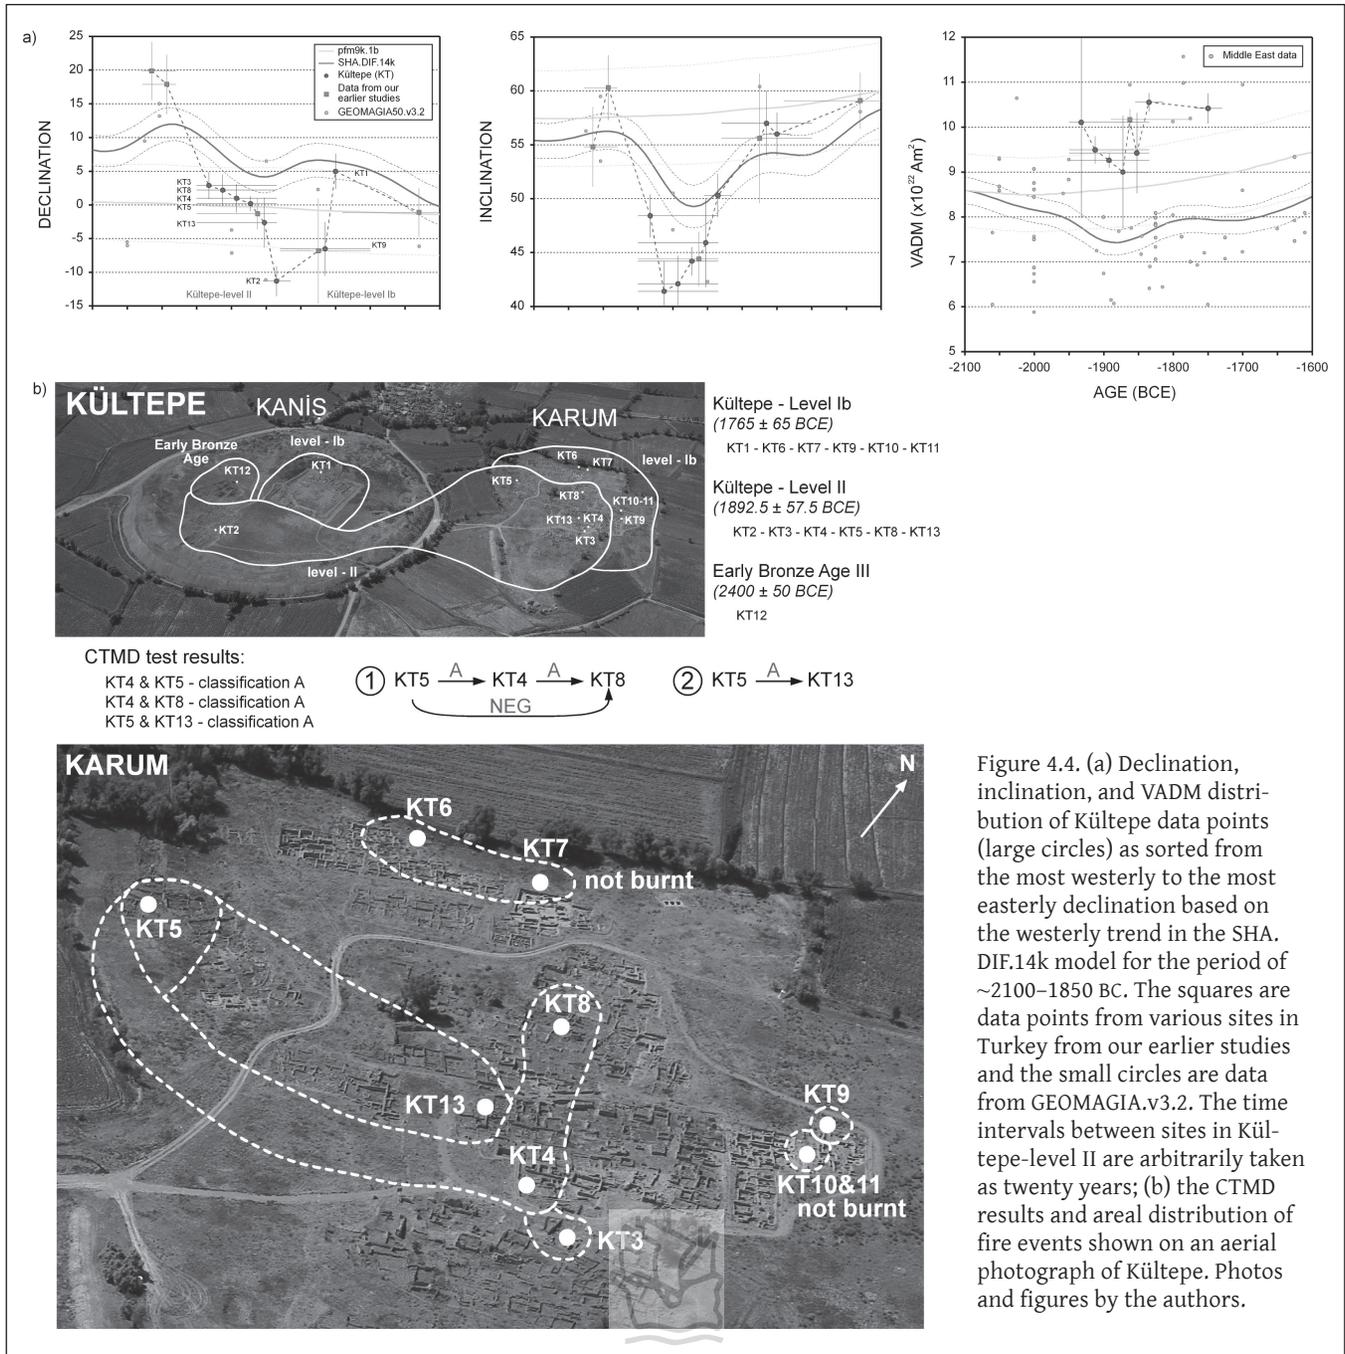

Figure 4.4. (a) Declination, inclination, and VADM distribution of Kültepe data points (large circles) as sorted from the most westerly to the most easterly declination based on the westerly trend in the SHA. DIF.14k model for the period of ~2100–1850 BC. The squares are data points from various sites in Turkey from our earlier studies and the small circles are data from GEOMAGIA.v3.2. The time intervals between sites in Kültepe-level II are arbitrarily taken as twenty years; (b) the CTMD results and areal distribution of fire events shown on an aerial photograph of Kültepe. Photos and figures by the authors.

observations. Hence, these new results are very useful to improve the resolution of the models since there is a lack of directional data for this time period. Only sixteen records are available in GEOMAGIA50.v3.2 for the seven-hundred-year period 2200–1500 BC, from Greece to Azerbaijan, and from Moldavia/Ukraine to Egypt. Our nine (out of thirteen) new directional records in this time interval plus earlier results almost double the database for this entire region. In addition, these high quality data sets contribute in terms of a better spatial distribution. This will reduce any bias (the local varia-

tions in the field) introduced by the few existing data sets, considering that the majority of the GEOMAGIA50.v3.2 data is coming from Eastern Europe, some from the Near East, and very few from the Middle East.

From a total of forty-nine TT and MW measurements, forty were successful, yielding a success rate of 83 per cent which is exceptionally high regarding the overall rate of Thellier type archaeointensity experiments. The results are coherent between samples and methods. Although the cooling rate experiment was not performed, the agreement between microwave (cool-

ing time of 10–100 seconds) and thermal Thellier-type experiment's (cooling time of 10–100 minutes) results suggest that the cooling rate effects are minimal.

To be able to make a valid comparison with the existing data (GEOMAGIA.v3.2) and the global field models (SHA.DIF.14k and pfm9k.1b), the intensity results are converted into virtual axial dipole moments (VADM).

Our data from the period 2600–1700 BC (including those of our earlier study) are always significantly higher than predicted by the SHA.DIF.14k model based on archaeomagnetic and lava flow data, and generally higher than predicted by pfm9k.1b (Fig. 4.4a) but they are not in disagreement with published data²³ that support the existence of short-lived periods with high intensities, at least as observed in the Levant.

Relative Chronology of Fire Events in Kültepe

We have analysed the directional results of Kültepe to determine if they can be attributed to the same distribution or not. This allows us to assess whether the fire events at the site belong to a single big catastrophic event or to different (temporal) events. We used the common true mean direction (CTMD) test developed by McFadden and McElhinny.²⁴ The test is classified as A, B, C, or indeterminate.

The sets KT4 & KT5, KT4 & KT8, and KT5 & KT13 share a CTMD with classification A. The rest of the correlations are negative. Based on the results of Kültepe-level II, the areal distribution of fires is plotted in Figure 4.4b. As can be seen from the figure, KT2, KT3, and KT9 are from local fires whereas KT4 & KT8 and KT5 & KT13 are from larger scale fires. Therefore, we can conclude that the ages of fires in Kültepe are different and the site was not abandoned as a result of a big catastrophic fire event as was previously suggested by Sagona and Zimansky.²⁵

To establish a relative chronology for the fire events in Kültepe-level II (KT2, KT3, KT4, KT5, KT8, KT9, and KT13), we sorted the data based on their CTMD results and then on easternmost to westernmost declination. This best reflects the trend in the SHA.DIF.14k model at this time interval (Fig. 4.4a). In this scenario, the oldest/

youngest age — within the age errors — is assigned to the most westerly/easterly declination while the time span between each fire event is arbitrarily divided into equal time intervals of twenty years. The corresponding inclination values agree fairly well with the trend of the model but in this scenario declinations are more westerly towards ~1850 BC while inclinations are steepest around 1900 BC. Although we have 'smoothed' the directional changes by shifting the results within the time span allowed by the dating error, it seems that the model has not (yet) enough resolution to predict these short-term swings in directions. The magnitude and timing of these swings are however compatible with observations of secular variation over the past three thousand years.

The VADM trend is not helpful in discriminating the best possible sequence since values are very similar. They are essentially in accordance with the trend of the curve from the SHA.DIF.14k model but systematically higher, and they are largely in agreement with pfm9k.1b. Nevertheless, the scenario preferred here represents the most reasonable sequence of fire events at Kültepe, where the rate of directional variations is similar to secular variation as observed today. We do realize however that other scenarios are possible, and that the time constraints within the given age uncertainty do not allow this — or any other — scenario to be robust. For example, a scenario in which the data sets are sorted on increasing inclinations based on the mild increasing trend in the model, results in more abrupt changes compared to the first scenario, and the declinations display erratic jumps of 5–15° within ten-year time intervals. We favour the scenario outlined above (Fig. 4.4a) in which both declination and inclination change gradually and abruptly and unlikely erratic changes in the directions in such a short time interval are avoided.

Timing of Tilting of the Wall in Ilemma House

Among our sampling sets, one set was collected from a tilted mud-brick wall and its intact ignimbrite foundation stones (Fig. 4.1, KT8 samples from Ilemma House). As the acquisition of magnetization takes place during cooling, by analysing the directional results with and without a tilt correction (which is restoring the wall's present orientation to its original position), it is possible to determine if the tilting has occurred during the fire or long after. When the directions from KT8 are assessed with and without a tilt correction, the results

²³ For example: Ben-Yosef *et al.* 2009; Ertepinar *et al.* 2012; Shaar *et al.* 2011; Ertepinar *et al.* submitted.

²⁴ McFadden & McElhinny 1990.

²⁵ Sagona & Zimansky 2009.

are coherent with the expected directions and the directions from the ignimbrites only without a tilt correction, implying that the tilting — the collapse of the wall — must have occurred during the fire event.

Conclusions

This study concentrated on untangling the fire events in Kültepe. Not solely directions or intensities but the characterization of the full vector field is required for the most accurate interpretation. To assure that our samples are suitable for directional and intensity experiments, we first tested the rock magnetic properties and verified that most of the samples have ideal behaviour. The conclusions can be summarized as follows:

1. The directional results are highly coherent with the existing data in the literature and the global field model SHA.DIF.14k but the intensities are significantly higher than the model predictions.
2. The foundation part of a structure is not sufficiently heated, therefore, not ideal for archaeomagnetic studies.

5. The ignimbrites with two component demagnetization diagrams are heated up to a maximum temperature of 500 °C.

4. The collapse of the mud-brick wall in Ilemma House must have occurred during the fire event.

5. Based on the CTMD results, we propose that the timings of fire events are different and the abandonment of the site was not the result of a single catastrophic fire event.

Acknowledgements

We would like to thank the late Prof. Dr Kutlu Emre for her valuable feedback about Kültepe. We are also grateful to people in the excavation team who were helpful at all times. Particular thanks are due to Nuretdin Kaymakci, the drilling expert on fragile archaeological material.
